Abstract

This paper reports ZnPt bimetallic nanoparticles (ZnPtBNs) synthesis through the liquid phase deposition (LPD) of of Zn(NO$_3$)$_2$.6H$_2$O onto the indium-titanium oxide (ITO) substrates at various concentrations. The Effects of growth solution, the morphology, structural, and sheet resistance were studied. After preparation, the materials were characterized by using field emission electron microscopy (FESEM), energy dispersive X-ray (EDX), X-ray diffraction (XRD) and Four Point Probe (FPP) measurement by using Keithley 2401 source-meter. By inserting a growth solution into the ITO substrate the ZnPtBNs was successfully in-situ prepared. The synthesized ZnPtBNs exhibited homogeneous, fibrous at the (111) orientation with an average diameter of 100-700 nm. The atomic ratio of Zn:Pt and sheet resistance of ZnPtBNs decreased with the increase of Zn(NO$_3$)$_2$.6H$_2$O concentration. The optimal elemental composition of the sample was at a ratio of Zn:Pt (1:25) obtained at 0.467 mM of Zn(NO$_3$)$_2$.6H$_2$O. It showed the smallest sheet resistance (13.41 Ω) which was 38% lower than the ITO sheet resistance (18.44 Ω).

Keywords: Energy Dispersive X-Ray; ZnPtBNs; Four Point Probe; Sheet Resistance

INTRODUCTION

The microstructure, unique-morphology, and elemental composition of a counter electrode (CE) in the dye-sensitized solar cells (DSSCs) devices determine the charge-transferred, electrical conductivity, optical properties and the ohmic sheet resistance (Aberle, Wenham, & Green, 1993; Marjoni Imamora, 2014; Sulistiadji & Pitoyo, 2009; Suryono, 2012). Recently, research interest has shifted focus on platinum (Pt) as CE (Naumar et al., 2013; Sulistiadji & Pitoyo, 2009; Suryono, 2012; Tang et al., 2012; Umar, Yap, Awang, Salleh, & Yahaya, 2013) due to its high electrical conductivity, chemical stability, obtained quickly, and availability (Umar & Yap, 2013). However, an effort to further enhance the properties through a simple, cheaper, and environmental friendly method to environmental still remains as
important issue, especially in the field of nanotechnology (Amrullah, 2016; Y.-L. Lee et al., 2010; Sulistiadji & Pitoyo, 2009; Umar, Yap, Awang, & Salleh, 2017).

An introduction of another metallic material into Pt to form bimetallic nanoparticles has been extensive used in the previous report. They include AgPt (Mulyadi, 2010), CuPt (Umar et al., 2017), AuPt, PdPt (Mulyasa, 2006), etc. The Pt nanoparticles in the bimetallic form have unique properties, such as excellent optical, electronic, and electrical (Ali Oemar, 2008; Kurnia, Imamora, & Maiyena, 2019; Sabri, 2010). Besides, the Zn as a metallic material that has good electrical conductivity, excellent availability, anti-corrosion, and low-cost materials could enhance the initial conductivity of the Pt, and at the same time introduce new bimetallic elements as a counter electrode in DSSC devices (Y.-L. Lee et al., 2010; Marjoni Imamora, 2014; Yin, Zhang, & Zeng, 2008).

There are several well-known methods to synthesize Pt nanoparticles, namely reduction of metal precursors, dry plasma reduction, electrochemical deposition, and direct growth of metal on substrates by using the liquid-phase deposition method (LPD) (Chang, Oyama, & Hirao, 2006; Farasdaq; Li et al., 2008; Moraes, Saito, Leite, Massi, & da Silva Sobrinho, 2016; Mulyasa, 2006; Umar et al., 2017; Yoon, Vittal, Lee, Chae, & Kim, 2008). Among these methods, LPD is often used to produce Pt nanoparticles (Kharisov, 2008; Sulistiadji & Pitoyo, 2009; Umar et al., 2017).

This paper reports preparation of the fibrous ZnPt bimetallic nanoparticles (ZnPtBNs) by controlling the concentration of Zn(NO$_3$)$_2$.6H$_2$O, K$_2$PtCl$_6$, SDS, and formic acid by using the LPD method. The morphology of resulting samples was observed using FESEM. The shifts on the diffraction peaks were detected by the X-ray diffraction (XRD) spectra to confirm the formation of ZnPtBNs. Meanwhile, the elemental composition of the sample was obtained using the Energy Dispersive X-ray (EDX).

**METHOD**

**Preparation of ZnPtBNs**

The ZnPtBNs were prepared using the LPD method in deionized (DI) water. In the first process, clean ITO was put into the growing solution (15 ml) containing 1 mM of potassium hexachloroplatinate (IV) (K$_2$PtCl$_6$), 0.01 M sodium dodecyl sulfate, 1 mM formic acid and zinc nitrate Hexahydrate (Zn(NO$_3$)$_2$.6H$_2$O) at five concentrations (0.066, 0.200, 0.333, 0.467 and 0.660 mM). All chemical were purchased from Sigma Aldrich. The growth solution was stirred at 400 rpm for 6 h at 40°C. The ZnPtBNs were obtained on the surface of the ITO substrate. Next, ZnPtBNs was recovered and rinsed with DI water and dried at temperature of 70°C for 10 minutes.

**Characterization of ZnPtBNs**

The morphology of ZnPtBNs was characterized by using the FESEM (Zeiss Supra 55VP) at an acceleration voltage of 30 kV. Furthermore, the elemental composition of the ZnPtBNs on the ITO substrate was obtained using EDX. The X-Ray Diffraction (XRD) and FPP measurements were done using Keithley 2401 source meter, respectively.

**RESULTS AND DISCUSSION**

**Morphology of ZnPtBNs**

The fibrous ZnPtBNs were successfully synthesized on the ITO substrate. The FESEM images (see Fig. 1A-1E) show the bimetallic nanoparticles efficiently covered
the entire ITO substrates. The insets on respective of Figure 1A-1E show the change of ZnPtBNs morphology from cubic (inset of Fig. 1A), spherical (inset of Fig. 1B and 1C), and flowers (inset of Fig. 1D and Fig. 1E) structure with the particles size of 40-700 nm (see Fig. 1F). The Pt nanoparticles usually have morphology of cubic (H. Lee, Habas, Somorjai, & Yang, 2008; Sulistiadji & Pitoyo, 2009). They slightly changed to spherical (Kulesza & Faulkner, 1989), and flower-like form due to the increase of Zn(NO₃)₂·6H₂O concentration into the Pt as a host growth solution (Tang et al., 2012). The ZnPtBNs morphology also changed the miscibility, leading to the formation of new morphologies that are rough and fibrous. Besides, the obtained microstructure in the flower-like morphology was useful to enlarge an active surface area, making them more attractive as an excellent electrical conductivity material (Kharisov, 2008; Tang et al., 2012). However, the flower shape becomes more irregular and tends to damage to form smaller particles at addition of high Zn concentrations of >0.660 mM (see Fig. 1F). The crooked occurred as an effect of the saturation of Zn²⁺ attached to the Pt structure. The optimum, and homogeneous of fibrous flower ZnPtBNs morphology was successfully obtained at a concentration of 0.467 mM.

The EDX characterization of a selected ZnPtBNs is shown in Figure 2A, providing the elemental composition information of ZnPtBNs at five different concentrations (see Table 1). Table 1 describes the sample at a level of Zn had a comparative value, but with different atomic numbers due to the addition of Zn in nanoparticle ZnPt (Naitabdi et al., 2018). Interestingly, the increase in Zn(NO₃)₂·6H₂O level decreased the ratio Zn to Pt (see Table 1), which was in a good agreement with the FESEM analysis in Fig. 1A-IF. A high Zn and Pt ratio resulted in more hairy-

**Figure 1.** FESEM images of ZnPtBNs prepared by the addition of Zn(NO₃)₂·6H₂O at (in mM) **A.** 0.066, **B.** 0.200, **C.** 0.333, **D.** 0.467, **E.** 0.660, and **F.** The diameters of ZnPtBNs were obtained at such above concentration. The Insets show the corresponding enlarged FESEM images.
entities attach to the Pt, promoting the formation of the spherical and fibrous flower of ZnPtBNs, and leading gradual increment of the particles sizes with the Zn(NO$_3$)$_2$.6H$_2$O concentration increased as well (see Fig. 1F).

Figure 2B shows the XRD spectrum of ZnPtBNs. It shows that there were three XRD peaks of fibrous ZnPtBNs (JCPDS card number 03-065-3257) detected at diffraction positions of 2θ=40.08$^\circ$, 46.62$^\circ$, and 68.06$^\circ$ correspond to the crystal planed diffraction of (111), (200), and (220), respectively. These peaks seem similar to Pt diffraction peaks, namely 2θ=39.76$^\circ$, 46.23$^\circ$, and 67.45$^\circ$ (JCPDS card number 70-2057) associated with (111), (200), and (220) as well. These shifts of the diffraction peaks confirmed the formation of ZnPtBNs. Interestingly, the diffraction intensity of (111) crystal plane is higher than (200) and (220) suggesting that the ZnPtBNs growth was oriented to (111) plane, which was face-centered cubic (fcc) with a lattice of 3.89 Å. Besides, the diffraction intensity of (111) also increased at higher Zn(NO$_3$)$_2$.6H$_2$O concentrations. Such finding is a good agreement with the FESEM results shown in Figs. 1A-1E. Besides, the sample also detected another peaks at 2θ=21.54$^\circ$, 30.24$^\circ$, 35.22$^\circ$, 50.54$^\circ$, and 60.03$^\circ$, which are believed to originate from the ITO substrate.

Figure 3 shows the sheet resistance and average diameter of ZnPtBNs obtained at various Zn(NO$_3$)$_2$.6H$_2$O concentration. Based on FPP characterization results, the ZnPtBNs sheet resistance was proportional with the Zn concentration. Since the lower amount of Zn and Pt was an incomplete process at a low level of Zn(NO$_3$)$_2$.6H$_2$O, it caused higher amount of hydroxyl (OH$^-$) molecule, leading to a higher sheet resistance, as also reported earlier (Naitabdi et al., 2018). The increase of Zn(NO$_3$)$_2$.6H$_2$O amount resulted in the increasing amount of Zn$^{2+}$ reduced to a Zn$^0$ state at Pt (111). The electron transfer from n=2 to n=0 will be induced by OH$^-$. 
adsorption that took place as OH adsorption onto Zn at Pt(111) during the synthesis process (Igarashi, Aramata, & Taguchi, 2001). Such process is believed to reduce the number of hydroxyls (OH) at higher concentration of Zn(NO$_3$)$_2$.6H$_2$O concentration, resulting in a lower sheet resistance. However, as can be seen in Fig. 3 on the level of 0.200 mM, the sheet resistance of ZnPtBNs is quite low (14.13 $\Omega$), and then increases again to 229.03 $\Omega$ at a concentration of 0.333 mM. The instability of the trend represents the change of the structure (see Fig.1A-1E). The stable and the optimum sheet resistance value was obtained at a concentration of 0.467 mM ($\pm$13.41 $\Omega$), showing 38% lower than the ITO sheet resistance (18.44 $\Omega$). The finding is in a good agreement with FESEM analysis, where a concentration of 0.467 mM, the ZnPtBNs microstructure resulting from the fibrous flower form, leading the formation of larger an active surface area (Chen et al., 2011) and good electrical conductivity or lower sheet resistance (Yoon et al., 2008). These results are in line with an average diameter of ZnPtBNs, where it gradually increased with Zn(NO$_3$)$_2$.6H$_2$O concentration, promoting the formation of ZnPtBNs which had a larger surface area at (111) crystal plane (Hsieh, Wei, Hsiao, & Chen, 2012).

**Figure 3.** The sheet resistance and the average diameter (nm) as a function of Zn(NO$_3$)$_2$.6H$_2$O concentration.

**CONCLUSION**

The Effect of Zn(NO$_3$)$_2$.6H$_2$O concentration addition on morphology, structural, and electrical properties, especially sheet resistance of the fibrous ZnPtBNs prepared using the LPD method, have been successfully investigated. The morphology of fibrous ZnPtBNs was slightly changed from cubic to spherical, and hairy flower at higher due Zn(NO$_3$)$_2$.6H$_2$O concentration into the growth solution of Pt. The best morphology of the synthesized ZnPtBNs was a flower-like with homogeneous form, more fibrous with particle sizes ranging from 100-700 nm. The EDX and XRD results show the ratio of Zn to Pt decreases, and the diffraction intensity of (111) increases with the addition of Zn(NO$_3$)$_2$.6H$_2$O increased. The best atomic ratio of Zn: Pt of 1:25 and the lowest sheet resistance of 13:41 $\Omega$ were obtained at a concentration of Zn(NO$_3$)$_2$.6H$_2$O at 0.467 mM.
RECOMMENDATION
For further research, it can be done by varying the Sodium Dodecyl Sulfate (SDS), growth time, temperature and growing solution to obtain the new morphology of ZnPtBNs.
